Concurrent Constraint Programming
Based on Functional Programming
(Extended Abstract)

To appear in Proceedings of the 1998 European Joint Conferences on
Theory and Practice of Software (ETAPS), Lisbon, Portugal, LNCS,

1 Introduction

We will show how the operational features of logic programming can be added
as conservative extensions to a functional base language with call by value seman-
tics. We will address both concurrent and constraint logic programming [9, 2, 18]. As base language we will use a dynamically typed language that is ob-
tained from SML by eliminating type declarations and static type checking. Our
approach can be extended to cover all features of Oz [6, 15].

The experience with the development of Oz tells us that the outlined ap-
proach is the right base for the practical development of concurrent constraint
programming languages. It avoids unnecessary duplication of concepts by reusing
functional programming as core technology. Of course, it does not unify the
partly incompatible theories behind functional and logic programming. They
both contribute at a higher level of abstraction to the understanding of different
aspects of the class of programming languages proposed here.

2 The Base Language DML

As base language we choose a dynamically typed language DML that is obtained
from SML by eliminating type declarations and static type checking. Given the
fact that SML is a strictly statically typed language this surgery is straightfor-
ward. To some extent it is already carried out for the definition of the dynamic
semantics in the definition of SML [4].

There are several reasons for choosing SML. For the extensions to come it
is essential that the language has call by value semantics, sequential execution
order, and assignable references. Moreover, variants, records and exceptions are
important. Finally, SML has a compact formal definition and is well-known.
Since SML does not make a lexical distinction between constructors and variables, we need to retain constructor declarations. Modules lose their special status since they can be easily expressed with records functions.

Since DML is dynamically typed, the primitive operations of the language will raise suitable exceptions if some of their arguments are ill-typed. Equality in DML is defined for all values, where equality of functions is defined analogous to references.

Every SML program can be translated into an DML program that produces exactly the same results. Hence we can see SML as a statically typed language that is defined on top of DML. There is the interesting possibility of a programming system that based on DML offers a variety of type checking disciplines. Code checked with different type disciplines can be freely combined.

To provide for the extensions to come, we will organize the operational semantics of DML in a style that is rather different from the style used in the definition of SML [4].

3 Values

We distinguish between primitive values and compound values. Primitive values include numbers, nullary constructors, and names. Names represent primitive operations, reference cells, and functions. Compound values are obtained by record and variant construction.

We organize values into a first-order structure over which we obtain sufficiently rich first-order formulas. This set-up gives us a relation \( \alpha \models \phi \) that holds if an assignment \( \alpha \) satisfies a formula \( \phi \). An assignment is a mapping from variables to values. The details of such a construction can be found in [17].

4 States

A state is a finite function \( \sigma \) mapping addresses \( a \) to so-called units \( u \). Units are either primitive values other than names or representations of records, variants, reference cells, functions, and primitive operations:

\[
\begin{align*}
\{l_1 = a_1, \ldots, l_k = a_k\} \\
c(a) \\
\text{ref}(a) \\
\text{fun}(\text{Match}, \text{Env}) \\
\text{primop}
\end{align*}
\]

A match \( \text{Match} \) is a sequence of clauses \( (p_1 \Rightarrow e_1 \mid \ldots \mid p_n \Rightarrow e_n) \). An environment \( \text{Env} \) is a finite function from program variables to addresses.

For technical convenience we will identify addresses, names and variables occurring in formulas. We say that an assignment \( \alpha \) satisfies a state \( \sigma \) and write \( \alpha \models \sigma \) if for every address \( a \) in the domain of \( \sigma \) the following holds:
1. If $\sigma(a)$ is a primitive value $v$, then $\alpha(a) = v$.
2. If $\sigma(a)$ is a reference cell, a function, or primop, then $\alpha(a) = a$.
3. If $\sigma(a) = \{l_1 = a_1, \ldots, l_k = a_k\}$, then $\alpha(a) = \{l_1 = \alpha(a_1), \ldots, l_k = \alpha(a_k)\}$.
4. If $\sigma(a) = c(a')$, then $\alpha(a) = c(\alpha(a'))$.

Note that every state is satisfiable and that all assignments satisfying a state $\sigma$ agree on the domain of $\sigma$.

Our states and environments are different from the corresponding notions in the definition of SML. There environments map program variables to values and states map addresses to values. In our set-up environments map program variables to addresses and states map addresses to units. This means that our states represent both stateful and stateless information. Moreover, our states make structure sharing explicit. The sharing information is lost when we move from a state to a satisfying assignment. Given a state $\sigma$, the unique restriction of an assignment satisfying $\sigma$ to the domain of $\sigma$ is an environment in the sense of the definition of SML.

The relation $\sigma \models \phi$ is defined to hold if and only if every assignment that satisfies $\sigma$ also satisfies $\phi$. If the free variables of $\phi$ are all in the domain of $\sigma$, then we have either $\sigma \models \phi$ or $\sigma \models \neg \phi$. This means that a state has complete information about the values of its addresses. We require that the first-order language be rich enough so that for every $\sigma$ there exists a formula $\phi$ such that

$$\alpha = \sigma \iff \alpha \models \phi$$

for all assignments $\alpha$. Note that $\sigma$ determines $\phi$ up to logical equivalence. We use $\phi_\sigma$ to denote a constraint with the above property and say that $\phi_\sigma$ represents the logic content of $\sigma$.

5 Thread and Store

The operational semantics of DML distinguishes between a thread and a store. The thread is a functional evaluator that operates on the store. The states of the store are the states defined above. The store should be thought of as an abstract data type that is accessed by the thread only through a number of predefined operations. An example of such an operation is record selection, which takes an address $a$ and a label $l$ and returns an address or an exception packet.

An interesting primitive operation is the equality test $a_1 = a_2$. It returns $\text{true}$ if $\sigma \models a_1 = a_2$ and $\text{false}$ if $\sigma \models \neg a_1 = a_2$. Note that this definition yields structural equality for records and variants.

We write $\sigma \rightarrow \sigma'$ to say that there is an operation on the store that will replace the state $\sigma$ with a state $\sigma'$. The following monotonicity property holds for DML and all extensions we will consider:

$$\sigma \models \phi \land \sigma \rightarrow \sigma' \Rightarrow \sigma' \models \phi$$

provided all free variables of $\phi$ are in the domain of $\sigma$. 
6 Logic Variables

We now extend DML with logic variables, one of the essentials of logic programming. Logic variables are a means to represent in a state partial information about the values of addresses. Logic variables are modelled with a new unit lvar. The definition of states is extended so that a state may map an address also to lvar or an address. We only admit states $\sigma$ whose dereference relation $a \rightarrow_\sigma a'$ is terminating, where $a \rightarrow_\sigma a'$ holds iff $\sigma(a) = a'$. The case $\sigma(a) = a'$ may appear when a logic variable is bound. We use $\sigma'(a)$ to denote the unique normal form of $a$ with respect to the dereference relation $\rightarrow_\sigma$. The definition of the relation $\models$ is extended as follows:

1. If $\sigma(a) = lvar$, then there is no constraint on $\alpha(a)$.
2. If $\sigma(a) = a'$, then $\alpha(a) = \alpha(a')$.

States can now represent partial information about the values of their addresses. This means that $\sigma$ does not necessarily determine the truth value of a formula $\phi$ whose free variables are in the domain in $\sigma$.

Our states contain more information than necessary. For instance, if $\sigma(a) = a_1$ and $\sigma(a_1) = a_2$, then the difference between $\sigma$ and $\sigma[a_2/a]$ cannot be observed at the level of the programming language. In general, we impose the semantic requirement that for a state $\sigma$ and addresses $a_1$ and $a_2$ such that $\sigma \models a_1 = a_2$ the difference between $a_1$ and $a_2$ must not be observable. As it comes to space complexity, it is nevertheless important to model structure sharing.

The existing operations of DML are extended to the new states as follows. If an operation needs more information about its arguments than the state provides, then the operation returns the control value blocked. If there is only one thread, then computation will terminate. If there are several threads, the thread will retry the operation in the hope that other threads have contributed the missing information (see next section).

A match (e.g., $(x:\mathbf{x} = e_1 \mid \mathbf{nil} = e_2)$) blocks until the store contains enough information to commit to one of the clauses or to know that none applies. Of particular interest is the equality test $a_1 = a_2$, which we defined to return true if $\models a_1 = a_2$ and false if $\models \neg a_1 = a_2$. Since in the presence of logic variables $\sigma$ may entail neither $a_1 = a_2$ nor $\neg a_1 = a_2$, the equality test $a_1 = a_2$ may block. There is an efficient incremental algorithm [17] that checks for entailment and disentailment of equations $a_1 = a_2$.

We say that an operation is granted by $\sigma$ if it does not block on $\sigma$. All extensions we will consider will satisfy the generalized monotonicity condition:

$$\text{if } \sigma \text{ grants } o \text{ and } \sigma \rightarrow \sigma', \text{ then } \sigma' \text{ grants } o.$$  

The operation

$$\text{lvar: unit} \rightarrow \ 'a$$

creates a fresh logic variable and returns its address. The operation

$$\text{isvar: } 'a \rightarrow \text{bool}$$
returns `true` if its argument dereferences to a logic variable (i.e., \( \sigma(a) = \text{lvar} \)) and `false` otherwise. The variable binding operation

\[
\leftarrow: 'a \times 'a \rightarrow 'a
\]

expects that its left argument is a logic variable, binds it to its right argument, and returns the right argument. More precisely, if \( \leftarrow \) is applied to \((a_1, a_2)\) and \(\sigma(a_1) = a_3, \sigma(a_3) = \text{lvar} \) and \(\sigma(a_2) = a_4\), we distinguish two cases:

1. If \(a_3 = a_4\), then there is no side effect and \(a_4\) is returned.
2. If \(a_3 \neq a_4\), then the store is updated to \(\sigma[a_1/a_3]\) and \(a_4\) is returned.

The operation

\[
\text{wait}: 'a \rightarrow 'a
\]

is an identity function that blocks until its argument is bound to a nonvariable unit. This operation is useful for concurrent programming.

### 7 Multiple Threads

It is straightforward to extend DML with multiple threads. We use interleaving semantics, that is, the operations threads perform on the store do not overlap in time. Threads can be created with the expression

\[
\text{spawn } e
\]

which spawns a new thread evaluating \(e\) and returns \(()\). Often it is convenient to use the derived form

\[
\text{thread } e
\]

which expands to

\[
\text{let } \text{val } x = \text{lvar}() \ \text{in } (\text{spawn } x \leftarrow e); x \ \text{end}
\]

where \(x\) is a program variable that does not occur free in \(e\). For instance, if we want to evaluate the constituents of the application \(e(e_1, e_2)\) concurrently, we can simply write

\[
(\text{thread } e) (\text{thread } e_1, \text{thread } e_2)
\]

since the necessary synchronization comes for free.

The combination of logic variables and reference cells provides for powerful synchronization techniques. For this we need an operation

\[
\text{exchange}: 'a \text{ ref } \times 'a \rightarrow 'a
\]

which updates the reference cell given as first argument to hold the second argument and returns the previous content of the cell. Now a function

\[
\text{mutex}: (\text{unit } \rightarrow 'a) \rightarrow 'a
\]
that applies the function given as argument under mutual exclusion can be written as follows:

```ml
local val r = ref()

fun mutex(a) = 
    let val c = lvar()
    in wait(exchange(r,c));
    let val v = a() in c <- (); v end
end;
```  

A function

```ml
fun channel() = 
    let val init = lvar()
    val putr = ref init
    val getr = ref init
    fun put(x) = 
        let val new = lvar()
        val old = exchange(putr,new)
        in old <- x::new; () end
    fun get() = 
        let val new = lvar()
        val x::c = exchange(getr,new)
        in new <- c; x end
    in {put=put, get=get} end
```  

The put function puts items on the channel and the get function gets items from the channel. The get function blocks until there is an item on the channel. The blocking is caused by the match

```ml
val x::c = exchange(getr,new)
```  

To obtain fairness, the simple requirement that every thread that is not blocked will eventually advance suffices. In the two examples above starvation is excluded since the blocked threads are implicitly queued by means of logic variables. Note that both example functions encapsulate the logic variables they introduce. Our simple fairness requirement rests on the generalized monotonicity condition stated above (i.e., the property that a thread can advance cannot be invalidated by the operations performed by other threads). Languages that take channels as concurrency primitive (e.g., Pict [7]) require the more complicated fairness condition that our channels implement with logic variables.
The outlined style of concurrent programming originated with Oz and is explored in [15, 1]. The paper [15] relates to a previous version of Oz that did not have sequential composition. The book [1] is based on the current version of Oz and explores concurrent programming with object-oriented abstractions. The interested reader may also consult [19], which outlines a distributed version of Oz currently under development.

8 Unification

Next we define unification. We say that \( \sigma' \) is obtained from \( \sigma \) by a narrowing step if there are addresses \( a \) and \( a' \) in the domain of \( \sigma \) such that \( \sigma(a) = \text{1var} \), \( \sigma'(a') \neq a \), and \( \sigma' = \sigma[a'/a] \). Note that the variable binding operation \(<-\) performs a narrowing step if it succeeds. We say that \( \sigma' \) is obtained from \( \sigma \) by unification of \( a_1 \) and \( a_2 \) if \( \sigma' \) can be obtained from \( \sigma \) by a minimal number of narrowing steps such that \( \sigma' = a_1 = a_2 \) holds. If there is such a \( \sigma' \), we say that \( a_1 \) and \( a_2 \) are unifiable in \( \sigma \). If \( \sigma' \) is obtained from \( \sigma \) by unification of \( a_1 \) and \( a_2 \), then \( \phi_{\sigma'} \) is logically equivalent to \( \phi_\sigma \land a_1 = a_2 \). Moreover, \( a_1 \) and \( a_2 \) are unifiable in \( \sigma \) if and only if \( \phi_\sigma \land a_1 = a_2 \) is satisfiable. This logical characterisation of unification is a design principle and will also hold for the constraint extensions introduced in later sections.

The unification operation 
\[
==: \ 'a * 'a -> 'a
\]

expects that its two arguments \( a_1 \) and \( a_2 \) be unifiable. If this is the case, it narrows the state accordingly and returns \( a_2 \). Otherwise, it returns an exception packet.

Our states combine first-order constraints with higher-order functions and reference cells. Unification only concerns the part of a state that represents first-order constraints. Investigations of unification and constraint solving that relate to the unification defined here can be found in [3, 17].

9 Choices

An essential feature of logic programming is a built-in mechanism for search. To add this feature to DML, we introduce choice expressions of the form
\[
\text{choice } e_1 \mid \ldots \mid e_k
\]

A choice is evaluated by replacing it with one of its alternatives \( e_i \). To make this practical, the choices are tried from left to right employing chronological backtracking as in Prolog. We arrange things such that a speculative computation terminates with failure if a unification operation fails. If there is only one thread, this gives us the search mechanism of pure Prolog.

If there are multiple threads, we require that a choice is only committed once all other threads are either blocked or can only advance by committing a choice.
10 Spaces

The outlined Prolog-like search is not satisfactory in a concurrent setting since search is done at the top level and cannot be encapsulated into concurrent agents. It also fails to provide means for programming search engines like all solution search. This long-standing problem of logic programming is solved by Oz with a new concept called spaces. A space is a box consisting of a store and threads. Computation in a space is speculative and does not have a direct effect outside. Computation in a space proceeds until the space becomes either failed or stable. Stability means that no thread can advance except by committing a choice. There is an operation that blocks until a space is failed or stable and then reports the result. For stable spaces there are two possibilities: either there is a pending choice or not. If there is no pending choice, the space can be merged with the parent space to obtain the result of the speculative computation. If there is a pending choice, the space can be cloned and be committed to the respective alternatives.

Spaces turn out to be a simple and flexible means for programming search engines. A first version is described in [11, 14]. A recent paper on spaces and their use is [10].

11 Finite Domain Constraints

Finite domain constraints are constraints over integers that in conjunction with constraint programming yield a powerful tool for solving combinatorial problems like scheduling [2, 18, 12]. To include them in our framework, we introduce a new unit \texttt{lvar(D)} that represents a logic variable that is constrained to take a value in \texttt{D}, where \texttt{D} must be a finite set of integers. Variable binding and unification are adapted so that they respect finite domain constraints. The primitive operations of DML treat finite domain variables like unconstrained variables. There is a new primitive operation

\[
\texttt{fdvar: findom \rightarrow int}
\]

that returns a fresh logic variable constrained to the finite domain given as argument. Unification is extended to handle constrained logic variables according to their logical meaning. For instance, the expression

\[
\text{let val } x = \texttt{fdvar[1,2]} \text{ val } y = \texttt{fdvar[0,2]} \text{ in } x =/= y \text{ end}
\]

is equivalent to the expression \texttt{2}.

More expressive constraints like \texttt{2 \times x = y} are realized with concurrent agents called propagators. For instance, if the store knows that \(x \in \{1, \ldots, 10\}\) and \(y \in \{1, \ldots, 9\}\), a propagator for the constraint \(2 \times x = y\) can narrow the domains of \(x\) and \(y\) to \(x \in \{1,2,3,4\}\) and \(y \in \{2,4,6,8\}\). This form of inference is called constraint propagation. In general, there will be many propagators that communicate through the store. The power of a constraint programming system depends on the class of propagators it offers. Depending on the constraints they
realize, propagators often use nontrivial algorithms. A ubiquitous constraint is “$x_1, \ldots, x_k$ are all different”. For instance, if the store knows

$$x \in \{1, 2, 3\} \quad y \in \{1, 2, 3\} \quad z \in \{1, 2, 3\} \quad u \in \{1, 2, 3, 4, 5\} \quad v \in \{1, 3, 4\}$$

a propagator for “$x, y, z, u, v$ are all different” can narrow the domains to

$$x \in \{1, 2, 3\} \quad y \in \{1, 2, 3\} \quad z \in \{1, 2, 3\} \quad u \in \{3\} \quad v \in \{4\}$$

which determines the values of $u$ and $v$. There is a complete propagation algorithm for the all different constraint that has quadratic complexity in the number of variables and possible values [8].

12 Feature Constraints

Feature constraints are constraints over records that have applications in computational linguistics and knowledge representation. There is a parameterized primitive operation

$$\text{tellfeature}_\text{#label}: \text{record} * 'a \to \text{unit}$$

that constrains its first argument to be a record that has a field with the label $\text{label}$ and with the value that is given as second argument. For instance,

$$\text{tellfeature}_\text{#age}(x, y)$$

posts the constraint that $x$ is a record of the form \{age\=$y$, \ldots\}.

To accommodate feature constraints, we use units of the form

$$\text{lvar}(w, \{l_1 = a_1, \ldots, l_k = a_k\})$$

that represent logic variables that are constrained to records as specified. A record satisfies the above specification if it has at most $w$ fields and at least a field for every label $l_i$ with a value that satisfies the constraints for the address $a_i$.

There is also a primitive operation

$$\text{tellwidth}: \text{record} * \text{int} \to \text{unit}$$

that constrains its first argument to be a record with as many fields as specified by the second argument.

The operation $\text{tellfeature}$ is in fact a unification operation. It narrows the store in a minimal way so that the logic content of the new state is equivalent to the logic content of the old state conjoined with the feature constraint told. For instance, the expression

$$\text{let \ val \ x = lvar()} \quad \text{in} \quad \text{tellwidth}(x, 1); \text{tellfeature}_\text{#a}(x, 7); \ x \ \text{end}$$

is equivalent to the expression $\{a=7\}$.

Feature constraints and the respective unification algorithms are the subject of [17]. Feature constraints are related to Ohori’s [5] inference algorithm for polymorphic record types.
13 Conclusion

The main point of the paper is the insight that logic and concurrent constraint languages can be profitably based on functional core languages with call by value semantics. This avoids unnecessary duplication of concepts. SML wins over Scheme since it has richer data structures and factored out reference cells.

Our approach does not unify the theories behind functional and logic programming. It treats the extensions necessary for concurrent constraint programming at an abstract implementation level. To understand and analyse concurrent constraint programming, more abstract models are needed (e.g., [9, 2, 13, 15, 16]).

It seems feasible to extend the SML type system to logic variables and constraints. Such an extension would treat logic variables similar to reference cells. Feature constraints could possibly be treated with Ohori’s polymorphic record types [5].

The approach presented here is an outcome of the Oz project. The development of Oz started in 1991 from logic programming and took several turns. Oz subsumes all concepts in this paper but has its own syntax and is based on a relational rather than a functional core. The relational core makes Oz more complicated than necessary. The insights formulated in this paper can be used to design a new and considerably simplified version of Oz. Such a new Oz would be more accessible to programmers experienced with SML and would be a good vehicle for teaching concurrent constraint programming.

Acknowledgments

Thanks to Martin Müller and Christian Schulte for comments on a draft of the paper, and thanks to all Oz developers for inspiration.
