Abstract

We present a framework for the veriﬁed programming of multi-tape Turing machines in Coq. Improving on prior work by Asperti and Ricciotti in Matita, we implement multiple layers of abstraction. The highest layer allows a user to implement nontrivial algorithms as Turing machines and verify their correctness, as well as time and space complexity compositionally. The user can do so without ever mentioning states, symbols on tapes or transition functions: They write programs in an imperative language with registers containing values of encodable data types, and our framework constructs corresponding Turing machines.

As case studies, we verify a translation from multi-tape to single-tape machines as well as a universal Turing machine, both with polynomial time overhead and constant factor space overhead.

1 Introduction

Turing machines are, at least on paper, the foundation of modern computability and complexity theory, in part due to the conceptual simplicity of their deﬁnition. However, this simplicity leads to a lack of structure, which is also one of their biggest disadvantages: When it comes to detailed or formal reasoning, Turing machines soon become very hard to treat. This is maybe best reﬂected by the fact that while many basic areas of computer science, like logic, grammars, automata, or programming languages theory have been formalised in proof assistants, formalisations of even basic complexity-theoretic results\(^1\) are not available. While constructing Turing machines on paper might be possible, verifying a non-trivial machine deﬁned in terms of states and transition functions in a proof assistant is entirely infeasible.

There were several attempts of formalising Turing machines in proof assistants. Asperti and Ricciotti [2015] and Xu, Zhang, and Urban [2013] verify universal Turing machines in Matita and Isabelle/HOL, respectively, and Ciafﬁglione [2016] formalises the undecidability of Turing machine halting in Coq. However, none of these results analyse time or space complexity of their machines.

The main diﬃculty for detailed reasoning about Turing machines is their lack of compositionality. For example, it is not clear at all how to compose a two-tape Turing machine with a three-tape Turing machine that works on a diﬀerent alphabet. Therefore, it is common to rely on pseudo code or prose describing the intended behaviour. The exact implementation as well as its correctness or resource analysis is left as an exercise to the reader. In a mechanised proof, those details cannot be left out. Luckily, it is possible to hide those details behind suitable abstractions.

We present a framework that aims to have the cake and eat it too when it comes to mechanising computation in terms of Turing machines: Algorithms are stated in the style of a register based while-language; a corresponding Turing machine is automatically constructed behind the scene. Our framework furthermore characterises the semantics by deriving two relations for each machine, one witnessing partial correctness, which can subsume a space-consumption analysis, and one witnessing termination, which can subsume a running time analysis. These relations are similar to relations a Hoare-like logic would derive for the algorithm, especially in that they follow the internal structure of the program. The only task left for the user is to simplify those synthesised relations into a more high-level, hand-written description of the semantics.

Our imperative abstractions for Turing machines are shallowly embedded into Coq’s type theory: Primitive operations are predefined Turing machines performing primitive tasks. Control-ﬂow operators like If or While are Coq-functions constructing new Turing machines from existing ones.

To make reasoning and programming of Turing machines feasible, we introduce three layers of abstractions, \(L_1 \sim L_3\). The lower layers are heavily inspired by the deﬁnitions Asperti and Ricciotti [2015] use to formalise multi-tape Turing machines in the proof assistant Matita.

On the lowest layer \(L_0\) (which is actually not an abstraction), we deﬁne \(n\)-tape Turing machines \(M : TM^n_\Sigma\) over ﬁnite alphabets \(\Sigma\) and their semantics in Coq, based on the deﬁnitions by Asperti and Ricciotti.

Layer \(L_1\) introduces labelled machines \(M : TM^n_\Sigma(L)\), which additionally contain an arbitrary ﬁnite type \(L\) together with a function labelling every state of the machine with an element of this type. Based on this notion we deﬁne two veriﬁcation primitives: realisation (partial correctness) and termination. A labelled machine \(M : TM^n_\Sigma(L)\) realises a relation \(R \subseteq \text{Tape}^n_\Sigma \times (L \times \text{Tape}^n_\Sigma)\), written \(M \vDash R\), if for every terminating computation, the input tapes are in relation with the label of the terminating state and the output tapes. Dually, a

---

submitted for review, Saarbrücken, 2020
machine terminates in a running time relation $T \subseteq \text{Tape}_n^m \times \mathbb{N}$, written $M \downarrow T$, if for every related pair of input tapes $t$ and step counts $k$, the machine actually terminates in $k$ steps on input $t$. Realisation and termination can be used to express the correctness of a machine.

Programming machines on layer $L_1$ is quite hard because we have to define concrete transition functions. We thus introduce layer $L_2$ with primitive machines that can read, write and move the head as well as lifting operators and control-flow operators.

Lifting operators and control-flow operators can be used to compose machines. For example, given machines $M_1 : \text{TM}_m^n(L)$ and $M_2 : \text{TM}_m^n(L')$, we can use tape-lifting operators to obtain machines $M'_1 : \text{TM}_m^{n+m}(L)$ and $M'_2 : \text{TM}_m^{n+m}(L')$, and alphabet-liftings to obtain machines $M''_1 : \text{TM}_m^{n+m+1}(L)$ and $M''_2 : \text{TM}_m^{n+m+1}(L')$. We can then use control-flow operators to compose them into a machine $M''_1 \cdot M''_2 : \text{TM}_m^{n+m+1}(L'')$. From layer $L_2$ onward, we never need to consider machine states or transition functions again; we just compose machines and use the labelling function as an abstraction in the verification process.

On layer $L_3$, programming Turing machines is still very low-level, because we have to consider bare tapes. On layer $L_3$, we introduce the notion that a tape contains a value of an arbitrary encodable type, like natural numbers or lists over other encodable types. A tape may also be void, i.e. contain no value. We have primitive operators, for example to increase the value of a tape that contains a number, or to copy the value from one tape to another tape.

As case studies, we give a mechanisation of a translation from multi-tape to single-tape machines as well as a mechanisation of a universal Turing machine in Coq. Both machines have a polynomial time and constant factor space overhead. To the best of our knowledge, this is the first formalised universal machine verified w.r.t. time and space complexity for any model of computation in any proof assistant.

Definitions, lemmas, and theorems in the PDF-version of this document are hyperlinked with the accompanying Coq development; those links are marked by a \href-symbol.

**Structure**  
Section 2 introduces notation and type-theoretic preliminaries. Sections 3 to 6 give an overview over the layers $L_0$ - $L_3$. We report on the implementation of a universal machine in Section 7. We conclude by commenting on the mechanised proofs (Section 8), an overview of related work (Section 9), and a discussion of our results and future work (Section 10). Appendix A contains a full definition of Tring machines while Appendix B contains a translation from multi-tape to single-tape machines.

## 2 Preliminaries

We work in constructive type theory with inductive types and an impredicative universe of propositions.

We represent tapes following Asperti and Ricciotti [2012]:

### Definition 3.1.

Let $\Sigma$ be a type. We define

\[
\text{Tape}_\Sigma := \text{nulltape} \mid \text{leftof } r s \mid \text{midtape } l s m r s \mid \text{rightof } l l s \mid \text{with } l, m, r : \Sigma \text{ and } s, l s : \mathcal{L}(\Sigma).
\]

We leave out $\Sigma$ if the alphabet is clear from the context. We write $\text{Tape}_\Sigma^n$ for a vector of $n$ tapes. The representation does not specify an explicit blank-symbol. The constructors

The basic inductive types we use are the Booleans $\mathbb{B} := \{$ true, false $\}$, the unit type $\mathbb{1} := ()$, the natural numbers $\mathbb{N} := \{ 0 \mid n \in \mathbb{N} \text{ product types } X \times Y \text{, sum types } X + Y \text{, and the type with exactly } n \text{ elements } \mathbb{F}_n \}$. Given a type $X$, we further define options $\mathcal{O}(X) := \emptyset \mid \{ x \}$ and lists $\mathcal{L}(X) := \{ \} \mid x : A \text{ for } x : X \text{ and } A : \mathcal{L}(X)$. These notations are shared with vectors $\vec{x} : X^n$ of fixed length $n : \mathbb{N}$. We index elements of vectors $\vec{x} : X^n$ by indices $i : \mathbb{N}$, writing $\vec{x}[i]$. We write $f \circ A$ to map a function over a list, vector or tape. To inline case distinctions over inductive values inside formulas, we write match $s$ with $p_1 \Rightarrow r_1 | \ldots | p_l \Rightarrow r_l$ for pattern matching.

We encode relations as functions returning a proposition. Thus $\lambda(nm : \mathbb{N}). \text{true} \iff n \neq m$ defines the identity relation on natural numbers. We write $R \subseteq A \times B$ as an abbreviation for $R : A \rightarrow B \rightarrow \mathbb{B}$. $R_1 \circ R_2$ denotes relational composition, i.e. the relation $\lambda a b. \exists x. R_1 a x \land R_2 x b$. We oftentimes identify $\mathbb{1} \times B$ with $B$ and will thus identify relations $R \subseteq A \times (\mathbb{1} \times B)$ with relations $R \subseteq A \times B$.

We use a constructive notion of injections, namely retractions: A function $f : X \rightarrow Y$ is called a retraction, written $f : X \leftrightarrow Y$, if there is a function $f^{-1} : Y \rightarrow \mathcal{O}(X)$ s.t. $f^{-1}(f x) = [x]$.

We say that a type $X$ is discrete if there is a function $X \rightarrow X \rightarrow \mathbb{B}$ deciding equality. We say that a type $X$ is finite if it is discrete and there is an exhaustive list of elements $[x_0, \ldots, x_n]$. Note that for finite types there is a canonical numbering of elements of $x$.

### 3 Multi-tape Turing-machines ($L_0$)

Our approach to make reasoning about Turing machines feasible is to focus on what can be computed instead of how exactly it is computed in terms of states and transition functions: We give a few basic relations that are computable and ways to derive new computable relations by combining existing ones. We formalise this by a computability predicate $M \vdash R$, stating that the machine $M$ computes the relation $R$. Our framework contains combinators like the sequential composition $M_1; M_2$, and a proof that the relation computed by the sequential composition is the composition of the two relations computed by each $M_i$. This frees the user from the burden to verify Turing machines that are constructed in terms of state sets and transition functions.

The relations themselves relate the input to the result after executing a machine, i.e. a vector of tapes to a vector of tapes.

We represent tapes following Asperti and Ricciotti [2012]:
incorporate the position of the head and lead to a unique representation for any tape, not relying on blank symbols: midtape represents that the head currently is on some symbol \( m \) with remaining content further left and right in \( l_5 \) and \( r_s \), leftof (rightof) denotes that the head is on the left (right) end of the tape with remaining, nonempty content \( r :: r_s \), and niltape denotes an empty tape. The lists \( l_5, l_6 \) are ordered such that symbols closer to the head come first. If blank symbols are needed, they have to be specified explicitly.

The definition of tapes and multi-tape Turing machines is taken from Asperti and Ricciotti [2015]:

**Definition 3.2.** An \( n \)-tape Turing machine \( M : \text{TM}_n^\Sigma \) over a finite alphabet \( \Sigma \) is a tuple \( M = (Q, \delta, \text{start}, \text{halt}) \), where \( Q \) is the finite type of states, \( \delta : Q \times (\Sigma) \rightarrow Q \times (\text{Act}_\Sigma)^n \) (with actions \( \text{Act}_\Sigma := O(\Sigma) \times \text{Move and Move} := \mathbb{L} \mid \mathbb{R} \mid \mathbb{N} \)) is the transition function, \( \text{start} : Q \) is the initial state and \( \text{halt} : Q \rightarrow \mathbb{B} \) represents the halting states.

4  **Labelled Turing Machines, Correctness, and Termination (L₁)**

In order to abstract away from the state space of Turing machines, we introduce labelled machines:

**Definition 4.1.** A labelled machine over a type \( L \), written \( M : \text{TM}_n^\Sigma(L) \), is a dependent pair \((M', \text{lab}_M)\) of a machine \( M' : \text{TM}_n^\Sigma \) and a labelling function \( \text{lab}_M : Q_{M'} \rightarrow L \).

We identify unlabelled machines \( M : \text{TM}_n^\Sigma \) with unit-labelled machines \( M : \text{TM}_n^\Sigma(\mathbb{I}) \) and use the symbol \( M \) for both, relying on the context for disambiguation.

To reason about the semantics of Turing machines, we have two predicates, one for correctness and one for termination. Those notions use a predicate \( M(t, q) \triangleright k (q', t') \), denoting that \( M \) with the tapes \( t \) as input starting in state \( q \) will terminates in no more than \( k \) steps in the final configuration \((q', t')\). When we omit \( q \), we mean the initial state \( \text{start} \). We postpone the definition of \( \triangleright \) to appendix A as our framework enables reasoning to start on the level of correctness and termination.

For correctness, the realisation predicate uses a relation \( R \subseteq \text{Tape}_n \times (L \times \text{Tape}_n) \) to connect the input tape \( t \) to the label of the final state \( q \) and tape content \( t' \) reached after the execution of a machine:

**Definition 4.2.** Let \( M : \text{TM}_n^\Sigma(L), R \subseteq \text{Tape}_n \times (L \times \text{Tape}_n) \). \( M \triangleright R := \forall t k q t' . M(t) \triangleright k (q, t') \rightarrow R t (\text{lab}_M q, t') \)

For clarity, we often write \( M : \text{TM}_n^\Sigma(L) \triangleright R \) to specify the alphabet, number of tapes and label type simultaneously.

Since realisation states that if the machine halts, its result has certain properties, we need a second predicate for termination, incorporating the running time:

**Definition 4.3.** Let \( T \subseteq \text{Tape}_n \times \mathbb{N} \). \( M \downarrow T := \forall t k . T t k \rightarrow \exists c . M(t) \triangleright k c \).

The introduced predicates are (anti-)monotone:

**Fact 4.4.** The following hold:
1. If \( M \triangleright R' \) and \( R' \subseteq R \), then \( M \triangleright R \).
2. If \( M \downarrow T' \) and \( T' \subseteq T \), then \( M \downarrow T \).

For simple machines, a realisation predicate that entails termination in a constant number \( k \) of steps is useful:

**Definition 4.5.**
\( M \triangleright^k R := \forall t . \exists q t' . M(t) \triangleright^k (q, t') \wedge R t (\text{lab}_M q, t') \)

**Fact 4.6.** \( M \triangleright^k R \iff M \triangleright R \wedge M \downarrow (\lambda t k'. k \leq k') \)

We will just write \( \triangleright^k \) instead of giving the numerical value of the constant.

Note that space complexity is a correctness property and can be included in relations \( R \) for realisation. Since we do not have explicit blank symbols in our representation of tapes, the number of used cells never decreases, which means that the size of the result of a computation bounds the space usage during the computation, i.e. we can bound the space usage by a function \( f \) proving \( M \triangleright (\lambda t t'. t' | \leq f(|t|)) \), where \(|t|\) denotes the number of symbols on a tape. Our framework does not commit to whether the maximal size of tapes or the sum of the sizes shall be considered as space measure; in our verified machines, we choose to bound each tape individually. In Section 6 we will introduce more explicit support for compositional space analysis.

5  **Combining machines (L₂)**

In this section we define primitive machines, combinators to compose machines and lifting operations to change the number of tapes or the alphabet of a machine.

The idea is that every machine \( M \) defined using composition and lifting of primitive machines immediately is equipped with relations \( R_M \) and \( T_M \) and proofs \( M \triangleright R_M \) and \( M \downarrow T_M \). To prove that \( M \triangleright R \) for a different relation \( R \), a user only has to prove \( R_M \subseteq R \), and for \( M \downarrow T_M \triangleright \) by fact 4.4.

In the end, we obtain a shallowly embedded, composable, imperative programming language operating on tapes, where a user does not have to mention states or transition functions at all.

To keep this section short, we omit the precise constructions of machines \( M \) and only give their correctness relation \( R_M \) and running time relation \( T_M \).

5.1  **Primitive machines**

The machines that perform the most basic operations a Turing machine can do are given in Section 5.1, together with the most general relation they realise. Those relations use functions operating on tapes defined in appendix A. The fact that all those machines can run in a single step allows us to show termination and realisation in one step, by using \( \triangleright^k \).

Read is a 1-tape machine which returns in a final state that is labelled with the symbol under the head, if there is
We define machine combinators like sequential composition $\text{Switch}$, a case distinction operator $\text{Switch}$, and a 'do-while' operator While.

The semantics of e.g. sequential composition $\text{M}_1; \text{M}_2$ is easy to give informally: run $\text{M}_1$ and, on the resulting tape, run $\text{M}_2$. The correctness relation is then the composition of the correctness relations of the composed machines, e.g. if

$$M_1 : \text{TM}_2^\Sigma(\mathbb{L}) \models R_1 \text{ and } M_2 : \text{TM}_2^\Sigma(\mathbb{L}_2) \models R_2, \text{ then } M_1; M_2 : \text{TM}_2^\Sigma(\mathbb{L} \times \mathbb{L}_2) \models R_1 \circ R_2.$$

The running time relations can be composed by splitting the allowed running time between the two machines: If $M_1 \Downarrow R_1, M_1 \Downarrow T_1$, and $M_2 \Downarrow T_2$, then

$$M_1; M_2 \Downarrow (\lambda \ell. k. \exists k_1, k_2. T_1 \ell k_1 \land 1 + k_1 + k_2 \leq k \land \forall t \ell'. R_1 \ell t \ell' \rightarrow T_2 t' k_2).$$

Here, as the second machine only runs on results of the first machine, the correctness of the first machine can be used to weaken the requirement on the running time relation of the second machine.

The case distinction operator Switch takes as arguments a machine $M : \text{TM}_2^\Sigma(\mathbb{L})$ labelled over $\mathbb{L}$ and, for each possible label, another machine labelled over $\mathbb{L}'$, which is represented by a function $f : \mathbb{L} \rightarrow \text{TM}_2^\Sigma(\mathbb{L}')$. It runs $M$ first, and depending on the label $\ell$ returned by $M$, runs $f \ell$ on the resulting tape.

We specify Switch in Section 5.2. The finiteness of $F$ (the domain of $f$) is crucial here to encode $f$ into the finite state space of the resulting Turing machine.

In fact, sequential composition is a special case of Switch that does ignore the label of the first machine. The If combinator is also a special case of Switch (over Boolean labels), we thus leave it out here.

Loops can be implemented with the While $M$ combinator. It takes a machine $M$ labelled over $\mathbb{O}(L)$ and runs $M$ repeatedly as long as the resulting label is $\emptyset$. Once the label is $[\ell]$, While $M$ returns $\ell$. The correctness relation of While in Section 5.2 uses the following inductively defined relation:

$$\text{WhileRel} : \text{TM}_2^\Sigma(\mathbb{L}) \models \text{WhileRel} R$$

The first rule corresponds to returning when some label other than $\emptyset$ was produced, and the second rule corresponds to looping once more in the other case. To verify that some machine $M$ using While realises some relation $R'$, we would usually first find a relation $R$ realised by $M$. In a second step, one proves $R' \subset \text{WhileRel} R$, usually by some sort of inductive reasoning, and uses fact 4.4 to deduce that While $M$ realises $R'$.

Termination without running time could be obtained by requiring some sort of well-foundedness of the relation realised by $M$. For termination with time complexity, we use a co-inductively defined relation:

$$\text{Running Time for While}. \text{Assuming } M : \text{TM}_2^\Sigma(\mathbb{O}(L)) \text{ and realisation relations } R \text{ and running time relation } T \text{ (whose types fit for } M), \text{ we define the co-inductive}$$
with the same alphabet and number of tapes. To allow the Verified Programming of Turing Machines in Coq submitted for review, Saarbrücken, 2020

The combinators we have seen can only compose machines due to the co-inductive definition of $\text{WhileT}$ as $M$ and/or order of tapes. Assuming that we have an $n$-tape machine or relation by renaming them never actively used in the lifted machines.

The general idea is to extend the number of tapes (or alphabet) of a machine or relation by renaming them. The information how to reorder the tapes can be encoded as a duplicate free vector $\mathcal{I}$ containing $m$ elements of the finite type $\mathcal{F}_n$. The vector $[0, 3, 1] : (\mathbb{F}_3)^3$ can be used to convert a 3-tape machine into a 4-tape machine, where the 0-th is left unchanged whereas the first tape is now the third tape, the second tape is now the first and tape 2 of the resulting machine is unused.

The transition function of $\mathcal{I}_M$ uses $I$ to permute all read and write operations on the tapes accordingly. All of the tapes not mentioned in $I$ are never read or written in $\mathcal{I}_M$.

To add the corresponding rules to appendix A.1, we define tape-lifts for realisation and running time relations: We write $\mathcal{I}_r \mathcal{R}$ and $\mathcal{I}_t \mathcal{T}$ for them and point to definition A.10 for details.

The alphabet-lift $\mathcal{I}_d(M)$ changes a machine $M : \mathcal{T}_2^m(L)$ over an alphabet $\Sigma$ to a machine $\mathcal{I}_d(M) : \mathcal{T}_2^m(L)$ for any retraction $f : \Sigma \leftrightarrow \Gamma$ and default symbol $d : \Sigma$.

The idea of the alphabet-lift of a machine is to translate every read symbol using $f^{-1}$ and every written symbol using $f$; thus the transition relation of $M$, which originally operated on $\Sigma$, can now operate on $\Gamma$. Every read symbol which is not hit by $f$, e.g. for which $f^{-1}$ returns $\emptyset$, is translated to $d$. In practice, when constructing machines, one thus always wants that $M$ does not normally read $d$.

To complete Section 5.3, we again overload the alphabet-lift for relations, which we write as $\mathcal{I}_d(M) R$ and $\mathcal{I}_d(M) T$ and define in definition A.12.

During proofs, tape-lifts result in renaming some tapes and equalities of unmentioned tapes. To deal with many equations, we develop automation in Coq, for more details see Section 8. Alphabet-lifts that occur during the use of the abstractions presented in Section 6 are handled by our automation as well.

### 5.4 Verifying simple machines

As an example, we construct and verify the two-tape machine $\text{CopyLeft}$ which copies the symbol on the left of the head of tape 0 to the current position on tape 1.

**Definition 5.3.** We define $\text{CopyLeft} : \mathcal{T}_2^1$ as

$$\text{CopyLeft} := \begin{cases} \text{Move L} ; \\
\text{Switch (} \mathcal{I}_0 \text{ Read}) \\
(\lambda f : O(\Sigma)). \text{ match } f \text{ with} \\
| s \Rightarrow \mathcal{I}_1 \text{ Write } s \\
| \emptyset \Rightarrow \text{Nop} \end{cases}$$

To shorten the example, we will verify a weak relation that omits that all other cells on tape 1 remain unchanged and does not fully specify what happens if there is no symbol to read.

**Lemma 5.4.** $\text{CopyLeft} d_0 d_1 \equiv \text{CopyLeftRel}$ with

$$\text{CopyLeftRel} := \lambda t'. t[0] = t'[0]$$

$$\land \forall (s : \Sigma). \text{ current (move L t[0]) } = [s]$$

$$\Rightarrow \text{ current t'[1] } = [s]$$
We make this distinction between canonical alphabets and

\[ \Gamma_0 \{ \lambda \ t_0 \ t_1 \ t_1[0] = \text{tape\_move} \ L \ t_0[0] \} \]

\[
\circ ( \lambda \ t_1 \ ((\ell' : \Sigma), t_2).
\]

\[
\exists t_2 \ (\ell : O(\Sigma)). \ (\Gamma_0 \{ \lambda \ t_1 \ (\ell, t_2). \ \ell = \text{current}(t[0]) \land t_2 = t_1 \}) \ t_1 \ (\ell, t_2)
\]

\[
\land (\text{match } \ell \text{ with
\]}

\[
| s | \Rightarrow [\Gamma_1](\lambda \ t_2 \ t_3. \ t_3[0] = \text{tape\_write} \ s \ t_2[0]) \ t_2 \ t_3
\]

\[
| \theta \Rightarrow t_3 = t_2)
\]}

\[
\subseteq \text{CopyLeftRel}
\]

This inclusion follows by unfolding all definitions and basic logical transformations. \(\Box\)

We could prove the running time for CopyLeft in a similar fashion. Note that these kinds of proofs are very mechanical as long as no While loop is involved. We only need to unfold the relations and rewrite tapes, which can be automated in Coq. We will not detail more proofs of this kind on paper.

6 Generalised register machines (\(L_3\))

We now come to the highest layer of abstraction of our framework, where we treat Turing machines as abstract register machines. Each tape of such an abstract register machine contains a value of an encodable inductive type. We first define the notion of encodable types and tape containment, and then show how to specify machines constructing values. Afterwards, we show how case analysis can be implemented and give an exemplary implementation of addition and multiplication of natural numbers as abstract register machines.

6.1 Tapes as registers

\textbf{Definition 6.1.} A type \(X\) is encodable on \(\Sigma\) if there is an injective function \(\varepsilon : X \rightarrow \mathcal{L}(\Sigma)\), where \(\Sigma\) is a finite type.

For encodable types \(X\) we can define the size of elements \(x : X\) as the number \(|\varepsilon(x)|\). We can also define what it means for a tape \(t\) to contain a value \(x : X\). Note that there is always a canonical alphabet \(\Sigma X\) the type \(X\) is encodable on, introduced in the proof of encodability, but for any \(\Gamma\) with \(f : \Sigma X \rightarrow \Gamma\), \(X\) is by definition also encodable on \(\Gamma\). We make this distinction between canonical alphabets and extension via retraction explicit and define \(t \equiv_{f,k} x\). Here, \(x : X\), \(f : \Sigma X \rightarrow \Gamma\), \(k : \mathbb{N}\) is denoting the number of symbols on the tape irrelevant to the encoding and \(t\) is a tape over the alphabet \(\Gamma^+\), which extends \(\Gamma\) by symbols denoting the start and end of the encoding.

\textbf{Definition 6.2.} Let \(\Gamma\) be a type. We define

\[
\Gamma^+ := \text{START} \mid \text{STOP} \mid \text{UNKNOWN} \mid (s : \Gamma).
\]

\textbf{Definition 6.3.} Let \(X\) be encodable on \(\Sigma\), \(f : \Sigma \rightarrow \Gamma\) and \(t \in \text{Tape}_X\). We define

\[
t \equiv_{f,k} x := \exists t : \mathcal{L}(\Sigma). |x| \leq k \land
\]

\[
t = \text{midtape} \ t s \ \text{START} \ (f @ (\varepsilon(x))) \ + \ [\text{STOP}]\).
\]

Note that the length of the tape (and thus the space consumption of the machine up to this point) is exactly \(k+|x|+2\). If we write \(t \equiv_{x,k} x\), we mean that \(f\) is the identity retraction and thus \(t : \Sigma^+\). Explicitly mentioning the additional retract \(f\) is useful when combining machines over different alphabets: The alphabet-lift that are then required can be composed and stored into the retract, e.g., the relation \(\equiv_{(f,g,d)}(\lambda t \ t'. t'[0] \equiv_{f,k} x)\) is the same as \((\lambda t t'. t'[0] \equiv_{g^{-1} o f,k} x)\).

This enables our framework to hide alphabet lifts to the user.

The special symbol UNKNOWN is used globally as the default-symbol for the alphabet-lift. It is never read/written from/to a tape.

\textbf{Lemma 6.4.} The types \(\mathbb{I}\), \(\mathbb{B}\), and \(\mathbb{N}\) are all encodable. If \(X\) and \(Y\) are encodable, then \(O(X)\), \(\mathcal{L}(X)\), \(X + Y\), and \(X \times Y\) are encodable.

\textbf{Proof.} The type \(\mathbb{N}\) is encodable on the alphabet \(\Sigma^N := 0 \mid O:\)

\[
\varepsilon(0) := [0]
\]

\[
\varepsilon(S n) := S : \varepsilon(n)
\]

\(\Box\)

Using this definitions, we have

\[
\text{midtape} \ t s \ \text{START} \ [S, S, S, O, \text{STOP}] \equiv_{|x|} 3
\]

for all contents \(t s\) to the left — that is, we ignore garbage on the tape (apart from the length) and only require that to the right of the START symbol we have exactly an encoding and the STOP symbol. As an invariant, we will never consider empty tapes on the level of abstract register machines. This makes realisation proofs easier, because it restricts the shape of tapes. Thus, we define \(\text{isVoid}(t)\) to mean that \(t\) is non-empty and the head points to the rightmost symbol:

\textbf{Definition 6.5.} \(\text{isVoid}(t) := \exists m \ t s. t = \text{midtape} \ t s m \ \text{nil} \land |x| \leq k\).

We can now define our first abstract register machine, a machine that statically writes a value into a register given its encoding:

\textbf{Lemma 6.6.} Let \(X\) be encodable over \(\Sigma\) and \(\text{str : } \mathcal{L}(\Sigma)\). There is a machine \text{WriteValue}(\text{str}) : \text{TM}_X^\text{str} \ s.t.:

\[
\begin{align*}
\text{WriteValue}(\text{str}) & \equiv_{|\text{str}|+2} \ \lambda t \ t'. \\
\forall x. k. \varepsilon(x) = \text{str} & \Rightarrow \text{isVoid}(t[0]) \rightarrow t'[0] \equiv_{k-|\varepsilon(x)|-1} x.
\end{align*}
\]

Note that the machine takes a string instead of a value as static input to avoid parameterising the machine over encoding functions, which then is only necessary for the correctness statement.

Similarly, we can reset a tape which contains a value and make it void:

\textbf{Definition 6.7.} Let \(\Gamma\) be a type. We define

\[
\Gamma^* := \text{START} \mid \text{STOP} \mid \text{UNKNOWN} \mid (s : \Gamma).
\]

\textbf{Definition 6.8.} Let \(\Gamma\) be a type. We define

\[
\Gamma^* := \text{START} \mid \text{STOP} \mid \text{UNKNOWN} \mid (s : \Gamma).
\]
Lemma 6.7. Let $X$ be encodable over $\Sigma_X$ and $f : \Sigma_X \rightarrow \Gamma$. There is a machine $\text{Reset} : \text{Tm}^1_{\Sigma_X}$ s.t.:
\[
\text{Reset} \vdash \lambda t'. \forall xk. t[0] \equiv f, k x \rightarrow \text{isVoid}_{1+k+|\epsilon(x)|} t'[0]
\]

Lastly, we can change the retraction explicitly by inserting a translation machine which does not actually change tapes:

Lemma 6.8. Let $X$ be encodable over $\Sigma_X$ and $f, g : \Sigma_X \rightarrow \Gamma$. There is a machine $\text{Translate} f g : \text{Tm}^1_{\Sigma_X}$ s.t.:
\[
\text{Translate} f g \vdash \lambda t'. \forall xk. t[0] \equiv f, k x \rightarrow t[0] \equiv g, k x
\]

6.2 Constructor and Destructor Machines

Building on the previous definitions and machines we implement the two constructors of natural numbers:

Lemma 6.9. There is a machine $\text{ConstrO} : \text{Tm}^1_{\Sigma_0}$ s.t.
\[
\text{ConstrO} \vdash \lambda t'. \forall n. t[0] \equiv k n \rightarrow t'[0] \equiv k - 2 0.
\]

Proof. Define $\text{ConstrO} := \text{WriteValue}(0, 0)$. □

The $\text{S}$ constructor overwrites the current symbol (which is the start symbol) with $\text{S}$ and writes a new start symbol one step left.

Lemma 6.10. There is a machine $\text{ConstrS} : \text{Tm}^1_{\Sigma_0}$ s.t.
\[
\text{ConstrS} \vdash \lambda t'. \forall nk. t[0] \equiv k n \rightarrow t'[0] \equiv k - 1 \text{S} n.
\]

We now define the destructor machine for $\mathbb{N}$. As all destructor machines, it will analyse the head constructor on the tape, remove it and signal which constructor was found via labels. For the case of natural numbers, the destructor machine CaseNat reads a number from tape $t[0]$. If the number is 0, CaseNat leaves the number unchanged and terminates in the label false. Else, it decreases the number and terminates.

Lemma 6.11. There is a machine $\text{CaseNat} : \text{Tm}^1_{\Sigma_5}$ s.t. CaseNat $\vdash \lambda t (l, t'). \forall (n : \mathbb{N}). t[0] \equiv k n \rightarrow \text{match} l, n$ with
\[
\begin{align*}
\text{false,} & \quad 0 \Rightarrow t'[0] \equiv k 0 \\
\text{true,} & \quad S n' \Rightarrow t'[0] \equiv k + 1 n'
\end{align*}
\]

Proof. We implement the machine using Switch and Read:
\[
\begin{align*}
\text{CaseNat} := \\
\text{Move R} ; \\
\text{Switch Read} & \\
(\lambda(s : O(\Sigma_5^n)). \text{match s with} \\
\left[\begin{array}{l}
[S] \Rightarrow \text{Return}_{\text{true}} \text{ (Write START)} \\
[O] \Rightarrow \text{Return}_{\text{false}} \text{ (Move L)} \\
\_ \Rightarrow \_
\end{array}\right] \right)
\end{align*}
\]

We can implement and will use similar machines for Booleans (ConstrTrue, ConstrFalse, ConstrBool), options (ConstrSome, ConstrNone, CaseOption), and lists (ConstrNil, ConstrCons, CaseOption), but leave out their definitions in the paper.

Table 1. Tape assignment for Add and AddStep

6.3 Case Study: Addition and Multiplication

We now explain how to actually implement recursive abstract register machines. We will not require any direct operations on tapes and only use combinators from $L_2$ and constructors and destructors from $L_3$.

Recall that the While $M$ operator corresponds to ‘do-while’ in imperative languages, i.e. the machine $M$ has to decide at the end of its execution whether to continue or break out of the loop. Tail-recursive functions can easily be transformed into ‘do-while’ loops. Thus, when we translate functions to Turing machines, we first have to implement the function as a tail-recursive function.

As an example, we implement addition Add and multiplication Mult for natural step numbers.

The algorithm for addition can be described with the following pseudocode:
\[
\begin{array}{l}
\text{a} \leftarrow \text{n} \\
\text{b} \leftarrow \text{m} \\
\text{While} (b \neq 0) \{ \\
\quad \text{a}++ \}
\end{array}
\]

Reset $b$

The output tape is the tape that is represented by the variable $a$. First, we copy the input $n$ to this tape, and the number $m$ to an internal tape. In the loop, as long as we can decrease the copy of $m$, we increment $a$. After the loop, we reset the copy $b$ and the machine terminates. The first step in the design of the machine is to specify, which tape contains which variable. This is visualised in Table 1.

Because all parts of $\Sigma_5^n$ as the alphabet of Add and all its sub-machines.

The next step is to implement the step machine. AddStep has only access to the variables $a$ and $b$, stored on tape 0 and 1 (Table 1). The decrement operation and test whether $b$ was 0 is implemented using the deconstructor machine CaseNat. In the case that $b = 0$, the step machine terminates in $[0]$, so that the loop breaks. In case $b$ is greater than 0, CaseNat decreases $b$ and the step machine increases $a$. Then it terminates in $\emptyset$, so that the loop continues.

Definition 6.12. AddStep $:=$
\[
\text{If} ([[1] \text{CaseNat}) \text{Then} ([[[0] \text{ConstrS})) \text{Else} ([[[0] \text{Nop})
\]

Because all parts of AddStep terminate in constant time, we get the constant running time part of the semantics of AddStep for free.

Lemma 6.13. AddStep $\vdash^* \text{AddStepRel} :=$
We know that the loop is executed \(b \times t[1] \approx k_b \cdot b \rightarrow\) match \(l, b\) with
\[
\begin{aligned}
&[0], O \Rightarrow t'[0] \approx k_a \cdot a \land t'[1] \approx k_b \cdot b \\
&\emptyset, S \cdot b' \Rightarrow t'[0] \approx k_{a-1} \cdot S \cdot a \land t'[1] \approx 1 + k_b \cdot b'
\end{aligned}
\]
and \(l \approx 0\).

Proof. By fact 4.4 and induction on the structure of WhileRel. In the case the loop terminates, \(b \neq 0\) and \(t'[0] \approx a\), therefore \(t'[0] \approx a = a + 0 = a + b\). In the induction/loop case, we know that \(b = S \cdot b'\) and that \(t'[0] \approx S \cdot a \land t'[1] \approx b'\). By the inductive hypothesis, we know that \(t'[0] \approx b' + S \cdot a = a + b\) and \(t'[1] \approx 0\). \(\square\)

The running time of AddLoop must be shown separately. We know that the loop is executed \(b + 1\) times, and each iteration takes 9 steps. We have to add 1 step for each re-iteration of the loop. Thus, the total step number is \(9 + 10 \cdot b\).

**Lemma 6.15.** AddLoop \(\downarrow \lambda t. k\).
\[
\exists (a : b : N). t[0] \approx a \land t[1] \approx b \land 9 + 10 \cdot b \leq k
\]

Now we can define the full machine Add:

**Definition 6.16.** Add :=
\[
\begin{array}{llll}
\text{AddValue} & \cdot \text{AddValue} & \cdot \text{AddLoop} & \cdot \text{Reset}
\end{array}
\]

At this point, we introduce a graphical notation of execution protocols, that show the value of each tape after the execution of each sub-machine. In the left column, we have the input values for each tape, or \(\cdot\) if the tape is initially void. Each further column denotes the sub-machines. We write entries \(j : x\) in each cell that is in the index-vector of the sub-machine, where \(j\) is the tape-index of the lifted machine and \(x\) is the value after the execution of the sub-machine on this tape. We write \(j : \cdot\) when the tape \(j\) is void after the execution of the sub-machine. If a cell of the table is empty, then the tape has not changed, thus the current value is found further left in the same row. In Table 2, we have an example of an execution protocol for Add.

From the execution protocol in Table 2, we see that after the execution of all four sub-machines, the tapes 0 and 1 still contain the values \(m\) and \(n\), tape 2 contains \(m + n\), and tape 3 is void. Execution protocols serve as outlines of the formal correctness proofs. We conclude the correctness of Add.

**Lemma 6.17.**
\[
\begin{aligned}
\text{Add} \approx \lambda t t'. \forall m n k_0 k_1 k_2 k_3. \\
&[ t[0] \approx k_0 \cdot m \rightarrow t[1] \approx k_1 \cdot n \rightarrow \\
&\text{isVoid}(k_2(t[2])) \rightarrow \text{isVoid}(k_3(t[3])) \\
&\text{isVoid}(n) \cdot t[0] \approx k_0 \cdot m \land t'[1] \approx k_1 \cdot n \land t'[2] \approx k_2 + m - n - 2 \cdot (m + n) \land \\
&\text{isVoid}(n) \cdot t[0] \approx k_0 \cdot m \land t'[1] \approx k_1 \cdot n \land t'[2] \approx k_2 + m - n - 2 \cdot (m + n) \land
\end{aligned}
\]

For the running time function of Add, we have to add linear components for copying \(m\) and \(n\), a constant for Reset, and 1 step for each sequential composition operator.

**Lemma 6.18.** Add \(\downarrow \lambda t k. \exists m, n. t[0] \approx m \land t[1] \approx n \land \text{isVoid}(t[2]) \land \text{isVoid}(t[3]) \land 98 + 22 \cdot m + 12 \cdot n \leq k\).

When we prove the running time of sequences of multiple machines, we have to give running time functions for all suffixes of the sequence in terms of the sequence operator. We use the machine Add to implement a machine Mult that computes the multiplication function \(\mu : \mathbb{N} \rightarrow \mathbb{N}\).

We use the machine Add to implement a machine Mult that computes the multiplication function \(\mu : \mathbb{N} \rightarrow \mathbb{N}\) of \(\mu\). In the following, we also use the machine Add \(m\)-times to add \(n\) to a counter \(c\) that is initialised with 0. The following pseudo code presents the algorithm that we implement:
\[
\begin{aligned}
c &\leftarrow 0 \\
m' &\leftarrow m \\
\text{While} & (m' \rightarrow m) \\
& \{ \\
& c' \leftarrow \text{Add}(n, c) \\
& \text{Reset} c \\
& c \leftarrow c' \\
& \text{Reset} c' \\
& \text{Reset} m' \\
\}
\end{aligned}
\]

Note that we do not have to copy \(n\), since we do not write on \(n\) and the machine Add does not change \(n\). Also note that we cannot simply add \(n\) to \(c\), since input and output tapes are distinct. Therefore, we have to store the result of the addition to an intermediate variable (i.e. internal tape), which has to be reset afterwards.

MultStep, has only access to the copy of \(m\), which is mapped to tape 0 of MultStep. In the following, we also use the name \(m\) for its copy in the context of MultStep.

**Definition 6.19.** MultStep :=
\[
\begin{array}{l}
\text{If} \emptyset \cdot \text{CaseNat} \\
\text{Then} \text{Return}_0 \left( \text{Add}, \text{Reset}, \text{CopyValue}, \text{Reset} \right) \\
\text{Else} \text{Return}_1 \cdot \text{Nop}
\end{array}
\]

The correctness relation of MultStep is analogous to AddStep.

**Lemma 6.20.** MultStep \(\approx \) MultStepRel with

\[
\begin{array}{l}
\text{Return}_0 \cdot \text{Add}, \text{Reset}, \text{CopyValue}, \text{Reset} \\
\text{Return}_1 \cdot \text{Nop}
\end{array}
\]
Verified Programming of Turing Machines in Coq submitted for review, Saarbrücken, 2020

\begin{align*}
\text{MultStepRel} & := \\
\lambda t \cdot (t, t'), \forall (c m n : \mathbb{N}) k_0 k_1 k_2 k_3 k_4, \\
& \quad t[0] \equiv k_0 \text{ m} \rightarrow t[1] \equiv k_1 n \rightarrow t[2] \equiv k_2 c \\
& \quad \text{isVoid}_k t[3] \rightarrow \text{isVoid}_k t[4] \\
& \quad \text{match } \ell, m \text{ with} \\
& \quad \text{(\[(\ell, \ell, \text{O}) \Rightarrow t'[0] \equiv k_0\text{ m} \land t'[1] \equiv k_1 n \land t'[2] \equiv k_2 c \land \text{isVoid}_k t[3] \land \text{isVoid}_k t[4] \] \Rightarrow \text{AddStep} \text{MultStepRel} t[4])} \\
& \quad \text{match } \ell, m \text{ with} \\
& \quad \text{(\[(\ell, \ell, \text{S}) \Rightarrow t'[0] \equiv k_0 + m \land t'[1] \equiv k_1 n \land t'[2] \equiv k_2 - n + c \land \text{isVoid}_k t[3] \land \text{isVoid}_k t[4] \] \Rightarrow \text{AddStep} \text{MultStepRel} t[4])} \\
& \quad | \_ _ _ \Rightarrow \bot
\end{align*}

Note that for AddStep, we also prove termination in constant running time in lemma 6.13. This is not true for MultStep, because it calls Add, which has non-constant running time.

As usual, we define MultLoop := While MultStep. The correctness statement of MultLoop says that if the first three tapes contain \(m, n, c\), and all other tapes are void, then after the execution of the loop, the tapes contain \(0, n, m + n + c\) and the other tapes are void. Thus, when we instantiate the \(c\)-tape with the value \(0\), the output tape contains \(m \cdot n\).

\textbf{Lemma 6.21.} MultLoop \(\equiv\) MultStepRel with

\begin{align*}
\text{MultStepRel} & := \lambda t' \cdot \forall (c m n : \mathbb{N}) k_0 k_1 k_2 k_3 k_4, \\
& \quad t[0] \equiv k_0 \text{ m} \rightarrow t[1] \equiv k_1 n \rightarrow t[2] \equiv k_2 c \\
& \quad \rightarrow \text{isVoid}_k t[3] \rightarrow \text{isVoid}_k t[4] \\
& \quad t'[0] \equiv k_0 + m \land t'[1] \equiv k_1 n \land t'[2] \equiv k_2 - n + c \land \text{isVoid}_k t[3] \land \text{isVoid}_k t[4] \\
& \quad \text{Where } P \text{ and } P' \text{ are polynomials linear in } m, n, c, k_3, \text{ and } k_4.
\end{align*}

It is now easy to define the rest of Mult.

\textbf{Definition 6.22.} Mult :=

\begin{align*}
\text{\texttt{CopyValue}} \circ \text{\texttt{ConstrO}}; \text{\texttt{MultLoop}}; \text{\texttt{Reset}}
\end{align*}

It follows that Mult computes multiplication with time complexity in \(O(m \cdot n^2)\) and linear space overhead. We omit the detailed theories for brevity.

\section{Universal Turing machine}

In this section, we outline a universal Turing machine Univ. Univ expects as input the encoding of a single-tape Turing machine \(M\) and a tape \(t\) and computes the result of \(M\) on \(t\). Tape 0 is treated as a 'raw' tape, containing the tape of the simulated machine, while all other tapes are registers. For instance, tape 1 will contain an encoding of \(\delta_M\) while tape 2 will contain the encoding of the current state of \(M\). Instead of restricting to binary machines \(M\), we parametrise Univ over the tape alphabet of the machines that can be simulated.

The high-level outline of Univ is as follows: The machine Step first checks whether the current state is a final state and halts if this is the case. Otherwise, it reads the current symbol and looks up the action to be executed from the encoding of \(\delta\). After this, it executes the action on the object state and updates the tape for the current state. Ultimately, we will define Univ := While Step.

\textbf{Encoding of transition functions} \(\delta\) We encode states as tuples \(\mathbb{B} \times \mathbb{N}\). The Boolean encodes whether the state is a halting state. The number is a numerical representation for the machine state.

Transition functions \(\delta\) are encoded as an ‘association list’, i.e. a list \(L(A \times B)\), specifically with:

\(A := O(\Sigma_M) \times (\mathbb{B} \times \mathbb{N})\) \quad \(B := (O(\Sigma_M) \times \text{Move}) \times (\mathbb{B} \times \mathbb{N})\)

\(\Sigma_\delta\) is defined as the canonical alphabet that is used to encode this list.

We have a family of machines Lookup : \(\text{TM}\_\Sigma_{\Sigma(M)}^5\) (parametrised over alphabets \(\Sigma_X\) and \(\Sigma_Y\)), that looks up a value \(x\) in an associative list of type \(L(X \times Y)\). This machine is used in order to lookup the pair of the required actions and the successor state according to the transition function \(\delta\).

\textbf{Alphabet of Univ} For the definition of Univ, we follow a general practice for machines involving complex alphabets, which we demonstrate as an example here. The class of machines Univ : \(\text{TM}\_\Sigma_{\Sigma_{\text{Univ}}}^5\) is parametrised over an arbitrary alphabet \(\Sigma_{\text{Univ}}\). This alphabet has to ‘include’ some smaller alphabets that we need for the definition of Univ. In this case, we need an alphabet \(\Sigma_Y\) (for the encoding of \(\delta\)), and the alphabet \(\Sigma_M\) (the object tape). The ‘inclusion’ of these alphabets is specified by the user of Univ using retractions into \(\Sigma_{\text{Univ}}\), i.e. \(f_S : \Sigma_\delta \mapsto \Sigma_{\text{Univ}}\) and \(f_M : \Sigma_M \mapsto \Sigma_{\text{Univ}}\).

\textbf{Outline of Univ} We have some auxiliary machines that work directly on the object tape. We say that the object tape \(t : \text{Tape}_{\Sigma_{\text{Univ}}}\) contains the simulated tape \(t_M : \text{Tape}_{\Sigma_M}\) if \(t = (\lambda s. f_M s)@t_M\), and write \(t \equiv t_M\) in slight abuse of notation.\(^2\)

The auxiliary machine ReadCurrent : \(\text{TM}\_\Sigma_{\Sigma_{\text{Univ}}}^1(O(\Sigma_M))\) reads the current symbol from the object tape by reading its current symbol and mapping it to the alphabet of \(\Sigma_M\) using \(f_M^{-1}\). Similarly, the machine DoAction a executes an action \(a : O(\Sigma_M) \times \text{Move}\) on the object tape.

We also have auxiliary machines SetFinal b and IsFinal : \(\text{TM}(\mathbb{B})\) that set or get the Boolean in the encoding of a state.

The step machine Step : \(\text{TM}\_\Sigma_{\Sigma_{\text{Univ}}}^1(O(1))\) works as follows: it first uses IsFinal to check whether the machine is in a final state. If so, it will immediately terminate in the label \(\{1\}\). Otherwise, it will copy the read symbol from the object tape to an internal tape. It will then construct the pair \((c, v(q))\) and uses the machine Lookup to look up the pair \((\epsilon(q'), a)\) for this combination of read symbols and current state. It destructs the pair, executes the action, and stores the state \(q'\) as the current state. Finally, we define Univ := While Step.

Note that if we want an actual machine (for a given alphabet \(\Sigma_M\)), we have to instantiate the retractions \(f_S\) and \(f_M\). For\(^2\) Note that we implicitly map \(f_M s\) to the extended alphabet \(\Sigma_{\text{Univ}}^1\).
example, we can choose $\Sigma_{\text{Univ}} := \Sigma_S$ and $f_S := \text{id}$; there are multiple options to define $f_M$ (because $\Sigma_M$ occurred multiple times in $\Sigma_S$).

The correctness theorem states that if Univ contained a configuration $c$ of some machine $M : \text{TM}^1_{\Sigma_M}$, and if Univ terminated, then $M$ also terminates in some number of steps, and the tapes Univ encode the final configuration of $M$.

**Theorem 7.1** (Correctness of Univ).

$$\forall (M : \text{TM}^1_{\Sigma_M}) \ (t_M : \text{Tape}_{\Sigma_M}) \ (q : Q_M) \ (s_1 \ s_2 \ s_3 \ s_4 : \mathbb{N}).$$

$$t[0] \equiv t_M \land t[1] \equiv s_1 \ \delta_M \land t[2] \equiv s_2 \ \tau \to$$

$$\text{isVoid}_{\delta_1}(t[3]) \land \text{isVoid}_{\delta_1}(t[4]) \land \text{isVoid}_{\delta_1}(t[5]) \to$$

$$\exists (t'_M : \text{Tape}_{\Sigma_M}) \ (q' : Q_M). \ M(q, t_M) > (q', t'_M) \land$$

$$t'[0] \equiv t'_M \land t'[1] \equiv s_1 \ \delta_M \land t'[2] \equiv t[2] + (|Q_M| + \max c_M s_2) q' \land$$

$$\text{isVoid}_{\max c_M s_1 s_3} t'[3] \land \text{isVoid}_{\max c_M s_1} t'[4] \land$$

$$\text{isVoid}_{\max c_M s_1 s_2} t'[5], \ \text{where } c_M := |\epsilon(\delta_M)| + 1.$$

Here, note that regarding space, we have that every tape (except for the object tape) can be bounded by a constant depending on $M$. The object tape $t_M$ itself uses exactly the same number of symbols as in the simulated machine $M$, as it contains the same content.

The running time theorem of Univ states that if $M$ terminates in $k$ steps, then Univ will terminate in a certain number of steps if Univ’s input tapes contain the encoding of $M$’s initial configuration. Furthermore, we polynomially bounded the number of steps.

**Theorem 7.2** (Running time of Univ). For every alphabet $\Sigma_M$, there is a constant $c$ such that:

$$\forall (M : \text{TM}^1_{\Sigma_M}) (t_M : \text{Tape}_{\Sigma_M}) (t'_M : \text{Tape}_{\Sigma_M}) \ (q q' : Q_M) \ (k' : \mathbb{N}).$$

$$t[0] \equiv t_M \land t[1] \equiv \delta_M \land t[2] \equiv q_M \land$$

$$\text{isVoid}(t[3]) \land \text{isVoid}(t[4]) \land \text{isVoid}(t[5]) \land$$

$$M(q, t_M) > (q', t'_M) \land c \cdot (1 + k') \cdot |\epsilon(\delta)| \cdot |Q_M| \leq k.$$  

We summarise the above theorems:

**Theorem 7.3.** Univ is a universal Turing machine that simulates single-tape machines with constant space overhead and linear running time overhead.

Using the compiler from appendix B we can compile Univ to a class of single-tape universal Turing machines $\mathcal{U}$ (parameterised over an alphabet $\Sigma_M$) simulating other single-tape machines. Furthermore, if we see the compiler as an encoding for $n$-tape machines, we can define a class of single-tape universal Turing machines $\mathcal{U}$ $\mathcal{M}$ (again parameterised over an alphabet $\Sigma_M$) simulating multi-tape Turing machines.

### 8 Mechanisation in Coq

The development covered in this paper consists of ca. 19100 lines of code. That, ca. 4800 lines are various extensions of the standard library. The development of $L_0$ and $L_1$ take together 1158 lines, $L_2$ 2694 lines, and $L_3$ 3005 lines. The implementation of addition and multiplication takes 496 lines, whereas the multi-tape to single-tape compiler takes 2717 lines, and the universal machine takes 1844 lines. In total, we have a ratio of 51% to 49% specification vs. proofs (excluding libraries). We developed ca. 200 lines of new $\text{Ltac}$ tactics. The development takes about 5 minutes to compile on an Intel(R) Core(TM) i7-6600U CPU @ 2.60GHz machine.

Our project started in October 2016 and needed several re-implementations to serve as a basis for feasible implementations covering both time- and space-complexity. We had an almost finished implementation of levels $L_0$-$L_3$ not covering termination or any complexity analyses early on. This implementation however did parameterise every machine w.r.t. both tapes and an alphabet, which lead to very high compile-times and finally to unsolvable problems with deconstructor machines on level $L_3$.

We tried to keep the paper presentation faithful to the mechanisation. There are however several minor differences. For instance, we do not use the implicit coercion from machines to unit-labelled machines in Coq and always write
TM\_\mu\Sigma^n(L) explicitly. In some cases, it made sense to split type classes to decrease the size of proof terms. For instance, we do not capture injectivity in the type class for encodable types, because it is never technically needed, but only prove it as a lemma. More notably, we define tapes over arbitrary types \(X\) instead of finite types \(\Sigma\) for all definitions not making use of the finiteness. The definition of Turing machines then instantiates the alphabet with a finite type. This change had noticeable impact on compilation times: In dependent type theory, equalities take the type over which they are defined as argument. Finiteness proofs can be big, and rewriting with bigger proof terms can take longer time, making our change result in a significant speed-up since we rewrite with tape-equalities a lot.

Finite types in general proved to be a hurdle. We relied on the implementation by Menz [2016] in Coq. However, using a more mature implementation like that of mathcomp would have been more helpful, since we found ourselves going back to changing the implementation of finite types more than once. At the start of our project, the Coq ecosystem was not as mature as it is today, and the installation of third-party libraries was sometimes a hassle, which prevented us from using mathcomp.\(^3\) The ease of installing new libraries using opam would thus have spared us lots of work.

For realisation proofs, we developed a considerable amount of automation. Crucial for this were three tools: First, Sigurd Schneider’s smpl plugin\(^4\) which allows automated forward reasoning and simplification and is extendable by hints. Second, Coq’s tactic language Ltac, with the ability to introduce existential variables (so called evars). And third, Coq’s setoid rewriting facilities [Sozeau 2010]. In total, we are sure that implementing a project like ours in a proof assistant without tactics is infeasible.

The most advanced simplification tactic we use is called TMSimp. It destructs complex assumptions and simplifies the goal by exhaustively rewriting with all available equations between tapes. The tape equations can be considered the main antagonist in terms of usability and compile time in our framework, using them by hand is almost impossible, and the introduction of TMSimp eased our work on all levels.

9 Related Work

To the best of our knowledge, there are three mature mechanisations of Turing machines in the literature.

Ciaffaglione [2016] formalises the undecidability of the halting problem for Turing machines in Coq. They use a coinductive encoding of tapes. Since only a finite part of tapes is used in any computation, we were happy with our inductive characterisation.

Xu, Zhang, and Urban [2013] formalise Turing machines, Abacus machines and \(\mu\)-recursive functions. They obtain a universal Turing-machine by formalising a universal \(\mu\)-recursive function and verified compilers from \(\mu\)-recursive functions to Abacus machines and on to Turing machines. Abacus machines are a simple form of register machines which allow incrementation, decrementation and an unconditional jump operation. Xu et al. also verify that the halting problem of Turing machines is undecidable.

Asperti and Ricciotti [2012, 2015] formalise single- and multi-tape Turing machines over arbitrary finite alphabets in Matita [Asperti et al. 2011], an interactive theorem prover based on the same constructive type theory as Coq. They define a universal Turing machine as well as a translation from multi-tape to single-tape machines,\(^5\) and show the functional correctness and termination of their machines.

We build upon their work: We use almost the same definition of Turing machines in constructive type theory, and especially their representation of tapes as an inductive type is very useful, as it is canonical and abstracts away from the notion of blank cells used commonly on paper. We build upon their notion of realisability that specifies the semantics of a machine in terms of the relation that holds between the input and the output tape, and upon their idea of composing machines by using shallowly-embedded combinators.

We see four main improvements in our work:

First, we introduce the possibility to analyse time and space complexity of machines. Thus, both our universal machine and the compiler from multi-tape to single-tape machines have stronger specifications. In principle, since space complexity is a correctness property (for the definition of tapes used in their and our work), analysing space would have already been possible in Asperti and Ricciotti’s approach, but is not considered.

Secondly, our notions of encoding and containment allow constructions of Turing machines reading like programs in a while-language that supports (a finite number of) registers containing values of inductive types. This simplified the construction of our universal Turing machine considerably.

Thirdly, Asperti and Ricciotti use concrete final states of the implicitly constructed machines to handle the control flow in the ‘if’ and ‘while’ combinator. This breaks the abstractions their realisability framework provides, thus they define a second version of realisability that mentions a concrete ‘accepting’ state. Because we want to abstract away from the state space of machines, we introduce labelled Turing machines, with a labelling function mapping (final) states to the elements of an arbitrary type. Compositions of machines can now be specified w.r.t. their labels, and we never have to mention states.

Fourthly, Asperti and Ricciotti usually construct machines parametrically in the alphabet used. Similarily, the number of tapes of the constructed machines is a parameter. This means

\(^{3}\)In retrospect, we should have gone through the hassle.

\(^{4}\)https://github.com/sigurdschneider/smpl

\(^{5}\)where they just assume the correctness of certain machines rather than proving it (at least this is the case in the code shipped with Matita)
that when composing machines, each composed machine has to work with the same alphabet and the same number of tapes as the resulting machine. Therefore, a lot of basic machines are parametric in the number of tapes and the index of the different used tapes, which need to be given explicitly. We use the notion of liftings to extend tapes and the alphabet. The tape-lift significantly simplifies both the definition and verification of machines, whereas for the alphabet we think that the two approaches don’t differ considerably.

Furthermore, mainly by using automation tactics, we obtain an axiom-free development whereas Asperti and Ricciotti sometimes assume the correctness of machines similar to ones constructed before as an axiom.

Concerning other sequential models of computations, we are aware of the formalisation of register machines by Forster and Larchey-Wendling [2019] in Coq, which are proven equivalent to Diophantine equations [Larchey-Wendling and Forster 2019]. We believe that showing the equivalence of their register machines and our Turing machines would be relatively straightforward. Bayer et al. [2019] formalise a variant of register machines for their work-in-progress proof of the undecidability of Hilbert’s tenth problem in Isabelle.

There are various other formalisations of other models of computation. Norrish [2011] formalises the full $\lambda$-calculus in HOL light and proves the undecidability of the halting problem, besides various other computability-theoretic results. In a similar spirit, Forster and Smolka [2017] formalise the weak call-by-value $\lambda$-calculus in Coq and also formalise basic computability theory. Carneiro [2018] formalises $\mu$-recursive functions and similar basic computability results in Lean. Finally, Ramos et al. [2018] formalise the undecidability of a PVS-like functional language in PVS.

10 Discussion and Future Work

Asperti and Ricciotti [2015] set out with the goal to formalise complexity theory in a proof assistant, and accomplished to verify the correctness of a universal machine. We have gotten some steps closer to formalising actual complexity theoretic results by extending their results with time and space complexity, but are still nowhere near making formalisations of complexity theory feasible. With the current state of the art, neither simple examples nor actually interesting complexity theoretic theorems are in reach, much less results requiring oracles or nondeterminism. We are convinced that this is not due to the lack of powerful verification tools for Turing machines; but rather because Turing machines as model of computation are inherently infeasible for the formalisation of any computability or complexity theoretic result.

The most promising approach to formalising complexity theory in our eyes is to carry out formalised complexity theory in the $\lambda$-calculus, following formalisations of computability theory (e.g. by Forster and Smolka [2017]). For the most satisfying results, a complexity-theoretic equivalence between Turing machines and some form of $\lambda$-calculus should then be formalised, allowing results proved in the $\lambda$-calculus to be formally translated back to Turing machines. Forster and Kunze [2019] show in Coq that the weak call-by-value $\lambda$-calculus $L$ can simulate Turing machines with a linear time overhead, building on our definition of machines. Their translation also is linear in space (although that fact is not made formal in Coq). Similarly, Forster et al. [2019b] show that Turing machines can simulate $L$ with polynomial time and constant factor space overhead, using a rather involved simulation technique. In the current state of our framework, formalising this technique would take very long and would be at least daunting, but probably entirely infeasible.

What we have accomplished is to use the combinators from layer $L_2$ and the register operations from $L_3$ to obtain a relatively easy and explainable verification of a universal Turing machine w.r.t. to the notions of correctness and termination defined on layer $L_1$. The multi-tape to single-tape compiler explained in Appendix B did not make use of $L_3$.

For these large programs, proofs oftentimes became hard to navigate: The relations our framework derives follow the structure of the program. This is helpful in getting an intuition for proving these relations equivalent to shorter, problem-focused relations, but the equivalence proofs can become huge and involve a lot of tedious reasoning.

Coq’s kernel takes long to elaborate the verification of large machines like Univ. One problem is that the tape-lifting operator introduces equations between tapes, and the automation that tries to rewrite with them everywhere has bad asymptotic complexity. The equations cannot be simply removed, because they may still be needed in some later part of the proof. Furthermore, termination proofs have a similar structure as realisation proofs, but are too different to make generalisations or copy-and-paste approaches impossible.

Xu et al. [2013] employ a very low-level Hoare logic to verify their machines. For low-level verification, we actually found our realisation framework to be quite well-suited. In future work, we want to investigate a Hoare-logic with native support for realisation, termination, asymptotic time- and space complexity as well as value-containment. We have hope that this would make a simulation of the $\lambda$-calculus in Turing machines feasible.

We contribute our formalisation to the library of undecidable problems in Coq [Forster et al. 2019a]. Note that Appendix B contains a synthetic many-one reduction reduction from the halting problem of multi-tape Turing machines to the halting problem of single-tape machines. To connect the halting problem of single-tape Turing machines to other problems in the library, we translated the halting problem for machines $M : TM^1_2$ to the formalisation of single-tape machines used by Forster, Heiter, and Smolka [2018], thereby...
obtaining a reduction from halting to the Post correspondence problem.

References

A Semantics of Turing machine
We now give the semantics for Turing machines we omitted before.

Definition A.1 (Configuration). A configuration of $M : TM_{Σ^n}$ is a tuple $c = (q, t)$, where $q : Q_M$ and $t : Tape_Σ^n$. We write $Conf_M := Q_M × Tape_Σ^n$ for the type of configurations of $M$.

The function tape_move : Move → Tape_Σ → Tape_Σ moves a tape in a direction.

<table>
<thead>
<tr>
<th>Definition A.2 (Move movement).</th>
</tr>
</thead>
<tbody>
<tr>
<td>tape_move L (leftof rs)</td>
</tr>
<tr>
<td>tape_move R (rightof rs)</td>
</tr>
<tr>
<td>tape_move L (midtape nil m rs)</td>
</tr>
<tr>
<td>tape_move R (midtape ls m nil)</td>
</tr>
<tr>
<td>tape_move L (midtape l l m rs)</td>
</tr>
<tr>
<td>tape_move R (midtape m l m rs)</td>
</tr>
<tr>
<td>tape_move L (rightof l ls)</td>
</tr>
<tr>
<td>tape_move R (rightof l ls)</td>
</tr>
<tr>
<td>tape_move N t</td>
</tr>
</tbody>
</table>

Note that moving further right (or left) when that tape already is to the right (or left) of the symbols, does not change the tape.

The functions left, right : Tape → Σ* return the symbols to the left (or right) side of the head:

<table>
<thead>
<tr>
<th>Definition A.3 (Left and right).</th>
</tr>
</thead>
<tbody>
<tr>
<td>left (niltape)</td>
</tr>
<tr>
<td>right (niltape)</td>
</tr>
<tr>
<td>left (leftof rs)</td>
</tr>
<tr>
<td>right (leftof rs)</td>
</tr>
<tr>
<td>left (midtape l m rs)</td>
</tr>
<tr>
<td>right (midtape l m rs)</td>
</tr>
<tr>
<td>left (rightof l ls)</td>
</tr>
<tr>
<td>right (rightof l ls)</td>
</tr>
</tbody>
</table>

Now we can define the function tape_write : Tape_Σ → O(Σ) → Tape_Σ, that writes an optional symbol to a tape. When we write $[a]$, we get a midtape, where the left and right symbols remain unchanged and $a$ is now in the middle. For $\emptyset$, the tape remains unchanged. Note that there is no way to decrease the number of symbols on a tape or to write ‘blank’ symbols.

<table>
<thead>
<tr>
<th>Definition A.4 (tape_write).</th>
</tr>
</thead>
<tbody>
<tr>
<td>tape_write t θ</td>
</tr>
<tr>
<td>tape_write t [a]</td>
</tr>
</tbody>
</table>
Definition A.5 (current). The function current : Tape_\Sigma \to O(\Sigma) is defined by

\[
\text{current (midtape js ms rs)} := [m] \quad \text{current } := \emptyset
\]

We can now define the step function \( \text{step} : \text{Conf} \to \text{Conf} \).

Definition A.6 (step).

\[
\text{doAct } t(s, d) := \text{tape_move } d \text{ (tape_write } t s)
\]

\[
\text{step } (q, t) := \text{let } (q', \text{act}) := \delta(q, \text{map current } t) \text{ in } (q', \text{zipdoAct })
\]

Here, \( \text{zip} : \forall n A B C. (A \to B \to C) \to A^n \to B^n \to C^n \) is the zip-function on vectors.

To define the execution of a machine, we first define an abstract recursive function loop : \((A \to A) \to (A \to \mathbb{B}) \to A \to \mathbb{N} \to O(\text{Conf})\) for every \( A : \mathbb{T} \).

Definition A.7 (loop).

\[
\text{loop } f h a k := \begin{cases} [a] & h(a) \\ \emptyset & \neg h(a) \land k = 0 \\ \text{loop } f (f(a)) (k-1) & \neg h(a) \land k > 0 
\end{cases}
\]

We instantiate the abstract loop function and get a function loopM : \( \text{Conf} \to \mathbb{N} \to O(\text{Conf}) \) that executes \( k \) steps of the machine:

Definition A.8 (Machine execution). For a fixed machine \( M \), we define

\[
\text{initConf } t := (t, \text{start}_M) \\
\text{haltConf } (t, q) := \text{halt}(q) \\
\text{loopM } c k := \text{loop step haltConf } c k
\]

We write \( M(c) \xrightarrow{k} c' \) for loopM \( c k = [c'] \) and \( M(t) \xrightarrow{k} c \) for \( M(\text{initConf } t) \xrightarrow{k} c \).

A.1 Lifting operations

Concerning tape-lifts, we use the function select: For any \( m \)-vector \( I \) over indices \( < n \), it implements a function selecting \( m \) components from any \( n \)-vector \( V \):

Definition A.9 (Vector selection). Let \( X : \mathbb{T}, m, n : \mathbb{N}, I : \mathbb{F}^m_n \), and \( V : X^m \). Then select \( I V : X^n \) is defined by select \( I V := \langle \lambda(j : \mathbb{F}_m). V[j] @ I \rangle \).

This can now lift any realisation and running time relation by selecting the right subset of tapes from the larger, 'real' tapes, and plugging them in the smaller relation that gets lifted:

Definition A.10 (Tape-Lift of Relations). Let \( I : \mathbb{F}^m_n \) and \( R \subseteq \mathbb{F}^m \times (L \times \mathbb{F}^m_n) \) and \( T \subseteq \mathbb{F}^m \times \mathbb{N} \), then we define

\[
\begin{align*}
\int_I R := \lambda t (t', R(\text{select } I t))(t, \text{select } I t') \\
\int_I T := \lambda t k. T(\text{select } I t) k
\end{align*}
\]

Concerning alphabet-lifts, we need to translate symbols backwards using retracts. Therefore, we need a default symbol \( d \) for any symbol not covered by the retract.

Definition A.11 (Alphabet translation). For a retract \( f : \Sigma \to \Gamma \) and default element \( d : \Sigma \), the surject \( f d : \Gamma \to \Sigma \) is defined by

\[
\begin{align*}
\text{surject } f d \tau := \begin{cases} \sigma & \text{if } f^{-1}(\sigma) \neq \emptyset \\
\quad \quad d & \text{otherwise}
\end{cases}
\end{align*}
\]

The alphabet-lift of the relations then needs to translate the tape content from the larger, 'real' alphabet to the smaller alphabet used in the relation to be lifted. It does so by mapping surject over the tapes.

Definition A.12 (Alphabet-Lift of Relations). Let \( f : \Sigma \to \Gamma \) and \( d : \Sigma \) and \( R \subseteq \mathbb{F}^m \times (L \times \mathbb{F}^m) \) and \( T \subseteq \mathbb{F}^m \times \mathbb{N} \), then we define

\[
\begin{align*}
\int_{(f, d)} R := \lambda t (t', R((\text{surject } f d)(@t))(l, (\text{surject } f d)(@t'))) \\
\int_{(f, d)} T := \lambda t k. T((\text{surject } f d)(@t)) k
\end{align*}
\]

B Multi-tape to single-tape compiler

In the following sections, we will use tapes as registers, and we will be quite generous with the number of registers. It is a well-known fact that any \( n \)-tape Turing machine can be converted into an equivalent single-tape machine. In this section, we formalise such a compiler.

Given a labelled \( n \)-tape machine \( M_n : TM^n_\Sigma(L) \) we want to define a single-tape machine \( M_1 : TM^1_\Sigma(L) \) that simulates \( M_n \). This means that if \( M_1 \) terminates, so does \( M_n \), and vice versa. Additionally, the runtime overhead of \( M_1 \) is polynomial, and the space overhead is linear.

As in the literature (e.g. [Sipser 2006, p. 149]), we encode the vector of tapes on the single tape of \( M_1 \). The machine state of \( M_n \) is encoded in the machine state of \( M_1 \).

B.1 Encoding of tapes

We first have to address how \( M_1 \) encodes a vector of tapes on its single tape. We follow Sipser [2006] and choose to encode tapes as a delimited list of (encodings of) tapes. The alphabet of \( M_1 \) includes markers for the current symbols of each tape and delimiters for the encoded tapes.

We define functions \( \epsilon \) which encode vectors of tapes and tapes as strings. To encode vectors, every tape is delimited by
'nil' and the encoding of the entire vector of tapes is terminated by the symbol 'R':

\[
\begin{align*}
\epsilon \text{ nil} & \quad := [\text{R}] \\
\epsilon \text{ (t :: ts)} & \quad := \# \odot \epsilon(t) \oplus \epsilon(ts)
\end{align*}
\]

We still have to define how to encode a single tape as a string of symbols. Like Sipser, we have to mark the current symbol. However, there is a complication that is due to our tape model: On a multi-tape machine, moving the head one position after the rightmost symbol and back to the rightmost symbol on a tape does not change this tape at all. The encoding as a string has to reflect this property, in particular the length of the encoding must be invariant during head movement. The length of the encoding may only increase when we allocate a new symbol.

These constraints give rise to the following alphabet for the tape encoding:

\[
\Sigma_{\text{tp}} := \text{B} \mid \underbrace{\text{B} \mid \text{B} \mid \text{B} \mid \text{B}} _{\text{line}} \mid x \mid \underbrace{x \mid x \mid x \mid x} _{\text{line}} \quad (x : \Sigma)
\]

Underlined symbols denote that this is the current symbol of a tape. All encodings are delimited by the symbol \text{B} (for boundary) symbol, where the arrows indicate whether it is the left or right boundary. We then define the encoding of tapes as strings as follows:

\[
\begin{align*}
\epsilon \text{ (niltape)} & \quad := [\text{B}] \\
\epsilon \text{ (loftof } r \text{ rs)} & \quad := \text{B} :: r + rs + \left[ \text{B} \right] \\
\epsilon \text{ (midtape } l \text{ m rs)} & \quad := \text{B} :: \text{rev} \text{ ls} + m :: rs + \left[ \text{B} \right] \\
\epsilon \text{ (rightof } l \text{ ls)} & \quad := \text{B} :: \text{rev} \text{ ls} + [l, \text{B}]
\end{align*}
\]

For example, the tape encodings in the above mentioned manœuvre look like this:

\[
[\text{B}, a, b, c, \text{B}] \leadsto [\text{B}, a, b, c, \text{B}] \leadsto [\text{B}, a, b, c, \text{B}]
\]

We add the delimiter symbols 'nil' and 'R' to define the alphabet \(\Gamma\) of \(M_1\). Additionally, we use the symbol START and STOP to delimit the entire encoding of the vector of tapes:

\[
\Gamma := \sigma \mid \# \mid \$ \mid \text{START} \mid \text{STOP} \quad (\sigma : \Sigma_{\text{tp}})
\]

Note that START and STOP are in theory not necessary, but it simplifies the implementation.

When \(M_1\) starts, the head position is assumed to be on the START symbol. We then write \(t \approx \text{tps}\):

\textbf{Definition B.1} (Containment of tapes). Let \(t : \text{Tape}_1\) and \(\text{tps} : \text{Tape}_2\). Then:

\[
t \approx \text{tps} := t = \text{midtape [} \epsilon(\text{tps}) + [\text{STOP}]\text{]}
\]

B.2 Memorising While Loop

To ease the implementation of the translation we use a machine implementing a generalisation of both Switch and While. MemWhile \(f \cdot x_0\) allows memorising a label between loop iterations, without writing it to a tape. To pass values of the finite type \(X\) between iterations and ultimately return labels over \(Y\), a family \(f : X \rightarrow \text{TM}_2(X + Y)\) of machines labelled over the direct sum is required. The resulting machine is constructed in such a way that it first executes the machine \(f \cdot x_0\), returning labels in \(X + Y\). If this results in a label \(x : X\), the execution loops, and executes \(f \cdot x\) next. This is repeated until a label \(y : Y\) is produced, which denotes that the loop has finished and is the label the combinator returns. We omit the precise construction, realisation and running time relation this machine satisfies for brevity; they are a combination of the respective relations from Switch and While.

B.3 Implementation

The concrete implementation and verification is very technical; we only outline the definition of \(M_1\) in this paper.

As noted above, we want to encode the machine states of \(M_n\) in the state of \(M_1\). For that, we use the MemWhile operator. We have to give a function \(\text{Step} : Q_M \rightarrow \text{TM}_1(Q_M + L)\). After we defined the function \(\text{Step}(q)\), we define \(M_1 := \text{MemWhile} \text{Step (start}\_\text{tm}_1\text{)}\).

\[
\text{Step } q : \text{TM}_1(Q_M + L) \text{ is defined to be Return}_{\text{nil}(\text{lab}_{\text{tm}_1}q)} \text{ Nop if } q \text{ is a halting state of } M_n. \text{ That way, } \text{Step } q \text{ will terminate immediately with the right label. If } q \text{ is not a halting state, } \text{Step } q \text{ has to simulate one machine step of } M_n. \text{ For that, it first scans the single tape to construct the vector of all current symbols. Since the set of all possible vectors } cs : O(\Sigma)^n \text{ of current symbols is finite, we can store it in the state space of Step } q. \text{ Similarly, the computation of the tuple } (q', \text{acts}) = \delta_{M_n}(q, cs) \text{ can be encoded in the state space, where } q' : Q_{M_n} \text{ is the state in which } M_n \text{ transitioned and } \text{acts} : \text{Act}^n \text{ is the vector of actions that have to be executed on each tape. After executing these actions, } \text{Step } q \text{ terminates in the label inl } q', \text{ indicating that } M_1 \text{ will continue to execute Step } q' \text{ in the next loop iteration.}
\]

We use many auxiliary machines, like GoToCurrent, which starts at the \# symbol of an encoded tape and halts at the current (i.e. marked) symbol of the selected tape. The machine GoToNext : \(\text{TM}_1(\text{B})\) starts at the current symbol and either goes to the \# symbol of the next tape, or stops at $ and terminates in a state labelled with false, in the case that the head was already on the last tape.

For the auxiliary machines, the position of the tape head is an important part of their specifications. For example, we have a predicate atCons \(t \text{ tps}_1 \text{ tps}_2 \text{ tp}\) which states that the tape \(t : \text{Tape}_1\) of \(M_1\) is under a \# symbol and to the left there is the encoding of the tapes \(\text{tps}_1\); to the right, there is the encoding of the tape \(t : \text{Tape}_2\), and after this the encoding of the list of tapes \(\text{tps}_2\). We also have to maintain invariants like \(|\text{tps}_1| + 1 + |\text{tps}_2| = n\).

B.3.1 Reading all current symbols

In order to know which actions \(\text{Step } q\) has to emulate, it first has to scan all current (i.e. marked) symbols on the tapes.
The machine ReadCurrentSymbols : TM^1_1 O(Σ)^n scans the list of tapes from left to right and stores the read symbols in a vector, and counts how many symbols it has already read. Note that an exponential blow-up of the states of Step q (w.r.t. n) seems to be inevitable because ReadCurrentSymbols has to account for all permutations of read symbols.

In order to store all read symbols, ReadCurrentSymbols has to do some 'book keeping'. It uses the MemWhile operator, with O(Σ)^n × ℤ^n as the internal state type. The vector contains the already read symbols, and the index i is the number of tapes that have already been scanned. After executing GoToCurrent and GoToNext, it increases the counter and repeats the loop if GoToNext terminated on a # symbol. Otherwise, if the $ symbol was reached, the counter i must have been n − 1; ReadCurrentSymbols will then terminate in the state that is labelled with the complete vector of read symbols cs : O(Σ)^i.

### B.3.2 Executing actions

After ReadCurrentSymbols has read all symbols, we can use the state q and the vector cs on the meta level to access the vector acts : Act^n. The machine DoActions acts : TM^1_1 scans the tape again and executes each action. Similar to ReadCurrentSymbols, it keeps track of the index i of the current tape.

The interesting part is the machine DoAction a, which executes the action a : O(Σ) × Move.

Executing single actions consists of two steps: first, the current symbol is overwritten (if the O(Σ) is not 0), and then the move is performed. Moving the current symbol just amounts to toggling the 'underline' marking of two adjacent symbols, as we have shown in the above example. Writing is simple if we are not at a boundary symbol; we just have to overwrite the current symbol. However, in the case that we write on an underlined boundary symbol, we have to shift the entire tape content on one of the sides in order to append a new boundary symbol to the left or right. Here, we need the arrows over the boundary symbols, in order to know in which direction we have to shift the tape.

### B.3.3 Complete machine

Using the outlined machines ReadCurrentSymbols and DoActions, we can, for each step q, define a machine executing a step:

Step q :=
if halt q then Return_nop(lab_{M_n} q) Nop
else
Switch ReadCurrentSymbols
(λcs. Return_m(lab_{M_n}(δ(q, cs)))(MoveToStart;
DoActions(π_2(δ(q, cs))); MoveToStart))

Note that we use the meta-level 'if then else' here. If q is a halting state, the step machine will simply halt in the terminating state corresponding to the label of the state. The auxiliary machine MoveToStart moves the head from the $ symbol to the START symbol (the left-most symbol on the tape, which simply serves as a boundary symbol here). The loop function Loop : Q_{M_n} → TM^1_1(L) and the machine M_1 : TM^1_1 can now be finally defined:

Loop := WhileStep
M_1 := Loop init_{M_n}

The correctness statement says that whenever M_1 terminates, M_n also terminates given the encoded tapes with the same label as M_1:

<table>
<thead>
<tr>
<th>Theorem B.2 (Correctness of M_1).</th>
</tr>
</thead>
<tbody>
<tr>
<td>M_1 ⊨ (λt (ℓ, t'). ∀(tps : Tape^n_2). t[0] ≈ tps → \exists q tps'. M_n(tps) ≡ (q, tps') ∧ t'[0] ≈ tps' ∧ ℓ = lab_{M_n} q)</td>
</tr>
</tbody>
</table>

Note that, similar to our universal machine, the constant-factor space overhead follows as our tape encoding guarantees that, except for boundary symbols, every symbol on the tapes tps corresponds to symbols on t.

The termination statement says that if M_n terminates, then M_1 will also terminate when given the encoded of the tapes of M_n; and the running time of M_1 can be bounded by a concrete function. We have also shown that this running time function can be bounded by a polynomial.

<table>
